(Preliminary draft: March 2004)

Abstract

The factors behind the increase in the relative wages of skilled workers in developing countries are still not well understood. We use data from Peru to analyze the determinants of within industry share of skilled workers. We use a translog cost function for *gross* output and are therefore able to incorporate the effects of materials, both domestic and imported, in addition to capital. We find that capital accumulation can explain most of the increase in the wage bill share and relative wages of skilled labor. This is contrary to the commonly held view that unobservable technological change is responsible for the rising skill premium in both developing and developed economies. A test for separability indicates that a gross output cost function is the appropriate one to use and therefore share equations based on value added cost functions could be misspecified.

(*) The views expressed here are the authors' and not necessarily those of the Federal Reserve Bank of Atlanta or the Federal Reserve System.

Introduction

Many developing countries have experienced an increase in the relative wages of skilled workers following trade liberalization, as is well documented by now (see, for example, Robbins (1996), Wood (1997) and Hanson and Harrison (1999)). Since this is contrary to the predictions of standard Heckscher-Ohlin model of trade, skilled biased technological change has been cited as a possible explanation for this phenomenon¹. The fact that the rise in the skill premium has been observed in developing countries as well has also been interpreted as an additional piece of evidence to support the claim that it is technology rather than trade that is driving the rise in relative wages in the industrialized world (Berman and Machin (2000)).

A common way to demonstrate that skilled biased technological change has taken place is to show that the share of skilled workers in the wage bill *within* industries has increased over time (Berman, Bound and Griliches (1994), Berman and Machin (2000)). If the overall wage share of skilled workers in the economy is increasing due to trade then one would expect to see that reallocations of labor *between* industries (from those with a low wage share of skilled workers to those with higher wage shares) driving this shift. On the other hand, if technology were the culprit then these shares would be changing in the favor of skilled workers *within* industries. The papers cited above find that most the changes can be explained by within industry changes².

Changes in the wage share of skilled labor within industries can be a good measure of shifts in relative demand. An increase in the wage share of skilled labor in the face of a rising skilled wage premium will indicate a shift in favor of this type of labor, if we assume that the elasticity of substitution is greater than 1. The literature cited in the previous paragraph has attributed these wage share changes to technology. However,

¹ Other explanations include Davis (1996) and Feenstra and Hanson (1996). Davis argues that middle-income countries may be competing with low-income countries in a world with multiple cones of specialization and so trade could reduce relative wages in these middle income developing countries. According to Feenstra and Hanson, capital flows from the North to the South could increase the relative demand for skilled labor in both regions.

² Within industry changes in developing countries are stronger in the 1980s compared to the 1970s (Berman and Machin 2000)

within industry changes in the share can be driven by factors other than technology. Since technological change is not directly observable, the studies mentioned above interpret the residual component of share changes that cannot be explained by measurable factors as the effects of technology³. The factors other than technology that could also influence the shares of skilled and unskilled labor include capital and materials. Skilled labor could be more complementary with physical capital than unskilled labor. Griliches (1969) formalized the hypothesis for such capital-skill complementarity and provided evidence for it. Krusell et al. (2000), in fact, argue that capital-skill complementarity can explain most of the change in the share of skilled labor in the US (a view that is contrary to the rest of the literature). It is also possible for materials to affect the share of skilled labor. For example, material imports could substitute for unskilled labor in industrialized nations, as Feenstra and Hanson (1999) point out. While, the effect of imported materials could go the other way in developing countries, it may be necessary to take them into account to avoid misspecification.

So far, the effects of these other factors on changes in shares have been found to be small. Berman, Bound and Griliches (1994) find that capital can explain some of the change in favor of skilled workers but is able to account for only a small fraction of the shift. Berman and Machin (2000) also find that changes in capital intensity do not explain much. The effect of materials is usually not incorporated in these studies since they are based on cost functions for value added. Berman, Bound and Griliches (1994) try to take into account the effect of materials but find it to be unimportant.

The objective of this paper is to explore in detail the factors behind the increase in relative demand for skilled labor in a developing country – Peru. Our measure of relative demand will be the within industry share of skilled labor. Specifically, we want to see how much of the increase in relative demand is being driven by measured factors such as capital and materials compared to unobservable technology. It is interesting to conduct this exercise for developing countries for two reasons. First, capital accumulation is likely

³ Berman, Bound and Griliches (1994) do relate changes in share to indicators of technology such as investment in computers and R&D.

to be higher in developing countries compared to industrialized nations. If there are capital-skill complementarities then it is possible that capital accumulation can explain a larger fraction of the increase in demand for skilled labor in these countries compared to developed countries. The sample in the Berman and Machin paper does include developing countries. However, our paper conducts a more thorough analysis of the capital-skill complementarity issue in the following ways. We estimate the coefficient for capital intensity for Peru instead of using a calibrated coefficient from the literature as they do. Also, our data include information at a more disaggregated industry level and we take into account the effects of materials.

The second reason looking at developing country data may be interesting is that trade liberalization is likely to stimulate investment in these countries since a significant fraction of equipment in developing countries has to be imported. If capital-skill complementarities are found to be important then trade may increase the relative demand for skilled workers via this mechanism.

A paper that is closely related to ours is that of Pavcnik (2003). She uses Chilean plant level data from the late 1970s to the 1980s to analyze the determinants of the rising share of skilled workers and finds that investment played some role (she does not find any evidence that foreign technology had an effect). Our results are consistent with her findings, although we look at a more recent time period (the 1990s) for Peru. We find strong evidence for capital-skill complementarity. We estimate the contribution of capital accumulation to the increase in the overall wage share and relative wages of skilled workers and find it to be important. One way our analysis differs from hers is that we take into account the role of materials using a gross output cost function while Pavcnik uses a value added cost function as does most of the literature. Pavcnik does look at the effect of imported materials but it is introduced as an indicator of foreign technology. As we discuss in the paper, gross output based cost functions may be more appropriate. In that case the effect of imported materials has a different interpretation from the one in her paper.

Our main results are as follow. We find that increases in capital stock are strongly and positively related to increase in the wage share of skilled workers. Capital accumulation can explain most of the increase in share and relative wages of skilled labor. A test for separability indicates that a gross output cost function is the appropriate one to use. Share equations based on value added cost functions could suffer from misspecification.

The remainder of the paper is organized as follows. Section II gives a brief history of reforms in Peru in the early 1990s. It also presents the trends in wages and employment in Peru and shows that there has indeed been a shift in labor demand in favor of skilled labor during the decade of the 1990s. Section III presents the basic theoretical framework that provides the main determinants of the shares of skilled and unskilled workers in factor payments. Changes in these shares are interpreted as measures of relative demand shifts. The equation to be estimated and the estimation method are discussed in this section. Section IV describes the data and the results and shows that capital accumulation can explain a large fraction of the shift in demand in favor of skilled workers. The last section concludes.

II. Reforms overview and trends in wages and employment

Reforms in Peru

Like many other developing countries during last two decades, Peru implemented drastic reforms in early 1990s. Fujimori came to power in 1990 and implemented wide ranging structural reforms. His government eliminated price controls, subsidies and foreign exchange restrictions. A flexible exchange rate was adopted in August 1990. There was a significant liberalization of the foreign trade regime and the average level of tariffs was reduced sharply, from 66 percent in 1989 to 15 percent in 1995 and 12 percent in 1997. Import prohibitions, which were extensively used in the 1970s and the late 1980s, were gradually abandoned. Export restrictions were eliminated for most exports in 1991. There was also a substantial privatization drive and tax reform. After a recession in

1992, the country experienced GDP annual growth rates of more than 7 percent in the following five years. Inflation was much lower (average annual rate of around 20 percent) in the following five years.

Along with these reforms, Peru was one of the few countries in Latin America that implemented significant reforms in their labor markets⁴. These reforms were focused on lowering workers dismissal costs and facilitating temporary hiring, introducing certain flexibility in formal employment.

Prior to labor reform, labor legislation was extremely complex and included a wide range of regulations, such as binding minimum wage policies, extremely high dismissal costs, administrative controls, and specific compulsory benefits introducing a series of distortions in labor markets. Peruvian labor legislation was modified through successive steps. The Law of Employment Promotion (Ley de Fomento al Empleo) of 1991 along with a new Constitution in 1993 introduced several measures to reduce labor market rigidities. Later in 1995, new regulations followed to deepen the flexibility in labor markets. Consequently, workers dismissal costs declined sharply through the progressive elimination of job security regulations, the introduction of temporary contracts and changes in the severance payment structure.

Most of the effects of labor reform took place in 1991 and by 1995 labor markets seemed to have adjusted to new regulations. For example, the share of workers in private formal wage employment under temporary contracts increased from 20% in 1991 to 31% in 1992 and then to 40% in 1995. The increase from 1995 to 1997 was smaller (4 percentage points) compared to earlier years (Saavedra and Torero, 2000).

⁴ According to the 2004 IADB report, only six countries implemented significant labor reforms between the mid-1980s and 1999: Argentina (1991), Colombia (1991), Guatemala (1990), Panama (1995), Peru (1991) and Venezuela (1998).

Trends in wages and employment

In our paper, we focus on the period 1994-2000 after the major labor market reforms had already taken place in order to abstract from their effects. Focusing on this period also has the advantage that labor markets are closer to being competitive, which is the basis of our conceptual framework.

The dataset we use (described in greater detail in Section IV) has data on white and blue-collar workers for the manufacturing sector. White (empleados) and blue (obreros) collar workers will be interpreted as skilled and unskilled labor, respectively. Table 1 reports data on wages and employment of both types of workers for the manufacturing sector in Peru during 1994-2000. The relative wages of skilled workers increases from 2.04 to 2.52 over this period. Relative employment of skilled workers fell slightly from 0.66 to 0.64. The share of skilled workers in total wages increased from 0.57 to 0.62 over this period. The real wages of unskilled workers actually declined over this period while that of skilled workers increased by about 20%.

It is interesting to compare these trends with data for the US, an industrialized country. The annual increase in the skilled wage share (0.75 percentage points) in Peru between 1994 and 2000 is very similar to that of the US between 1979 and 1987 (see Berman, Bound and Griliches (1994)). The increase in relative wages is also comparable. The increase in relative wages in Peru implies that wages of skilled workers increased 3.5 percentage points faster per year than wages of unskilled workers. According to Bound and Johnson (1992), the relative wages of male college graduates to those of high school dropouts with less than 10 years of experience increased from 1.58 to 2.19 over the 1979-1988 period. This implies that wages of college graduates in the US increased 3.6 percentage points per year faster than that of high school dropouts. On other hand, the ratio of employment of skilled workers increased in the US during the 1979-1987 period (see Berman, Bound and Griliches (1994)) while we do not see much of a change in this ratio in Peru in the 1990s.

A substantial increase in the relative wages of skilled workers without a significant fall in the ratio of employment indicates an increase in the relative demand for this group of workers. We can use the methodology employed by Katz and Murphy (1992) to check whether there was indeed an increase in the relative demand for skilled workers and to estimate its size. If we assume a CES production technology with two factors then we get the following relationship

$$\log(\omega_1/\omega_2)=(1/\sigma)[D-\log(n_1/n_2)]$$

where ω is the relative wage (of skilled to unskilled) and n is the relative employment and period 1 is the latter period and σ is the elasticity of substitution between skilled and unskilled and D is the increase in relative demand for skilled labor.

The estimates of σ for the US reported in Hammermesh (1986) range from 0.49 to 3.7⁵. Applying these estimates to the equation above and using the numbers on relative wages and employment in table 1, we obtain estimates of D that range from 7% to 73% over the entire 1994-2000 period. An average of the two estimates of elasticity (i.e., 2.1) yields $D=40\%$. There has, therefore, indeed been a significant shift in demand in favor of skilled labor.

As Berman, Bound and Griliches (1994) point out, changes in the wage bill share of skilled labor are a good measure of relative demand shifts as long as the elasticity of substitution is greater than 1. We will focus on this measure in this paper. We perform a between-within decomposition of the wage bill share of the manufacturing sector to see if changes in the overall wage share of skilled labor are due to shifts across industries or because of changes within industries. The standard way to decompose these changes is as follows

$$\Delta S' = \sum \bar{S}'_i \Delta P_i + \sum \bar{P}'_i \Delta S'_i$$

where S' is the wage share of skilled workers for the manufacturing sector as whole, S'_i is the skilled wage share in industry i over this period, P_i is the share of industry i in total wages. A bar over a variable denotes the mean over the time period.

The results of the decomposition are reported in table 2. As is clear from the table, the change in the overall skilled share is due solely to within industry changes. The between industry change is actually negative. That is, it will be worthwhile to explore the factors behind these within industry changes if one wants to understand the relative demand shifts.

As mentioned before, it is possible that the changes in these shares are driven by measured factors such as capital and materials. Figure 1 shows the trends in these factors over time for the manufacturing sector in Peru. It is clear that capital stock has grown at much faster rate compared to the other variables. This is different from the US experience where the capital intensity did not change much over the 1979-87 period. The very large increase in capital intensity in Peru could therefore also drive the higher share of skilled workers.

III. Conceptual Framework

Our estimation is based on a quasi-fixed cost function for gross output. We will use this to derive equations involving shares of skilled and skilled workers in *factor payments* (all variable factors). The estimates from these equations will then be used to make predictions about changes shares in the *wage bill*. The quasi-fixed cost function assumes that some of the inputs are fixed and the quantities of the variable inputs are chosen to minimize costs. We will assume that the quasi-fixed or variable cost function takes the translog form (see Brown and Christensen (1981)) such as the following

⁵ These estimates are those obtained from cost function studies and are related to the substitution between *all* production and non-production workers.

$$\begin{aligned}
\ln CV = & \mathbf{a}_0 + \mathbf{a}_Y \ln Y + \sum_i \mathbf{a}_i \ln P_i + \sum_i \mathbf{b}_i \ln Z_i + \frac{1}{2} \mathbf{g}_{YY} (\ln Y)^2 + \frac{1}{2} \sum_i \sum_j \mathbf{g}_{ij} \ln P_i \ln P_j + \\
& \frac{1}{2} \sum_i \sum_j \mathbf{d}_{ij} \ln Z_i \ln Z_j + \sum_i \mathbf{r}_{Yi} \ln Y \ln P_i + \frac{1}{2} \sum_i \sum_j \mathbf{r}_{ij} \ln P_i \ln Z_j + \sum_i \Pi_i \ln Y \ln Z_i + \\
& \mathbf{a}_A \ln A + \frac{1}{2} \mathbf{a}_{AA} (\ln A)^2 + \mathbf{a}_{AY} \ln A \ln Y + \sum_i \mathbf{a}_{AP_i} \ln A \ln P_i + \sum_i \mathbf{a}_{AZ_i} \ln A \ln Z_i
\end{aligned} \tag{1}$$

where, Y is gross output, P_i is price of variable input i, Z_i is the quantity of fixed input i and A measures the level of technology.

We assume that there are four variable inputs and one fixed input. The variable inputs are skilled labor, unskilled labor, domestic materials and imported materials. The fixed input is capital.

The derivative $d \ln CV / d \ln P_i$ will equal the share (S_i) of the variable factor i in variable cost. Therefore, we have,

$$S_i = \frac{\partial \ln CV}{\partial \ln P_i} = \mathbf{a}_i + \mathbf{r}_{Yi} \ln Y + \sum_j \mathbf{g}_{ij} \ln P_j + \sum_j \mathbf{r}_{ij} \ln Z_j + \mathbf{a}_{AP_i} \ln A \tag{2}$$

where S_i is the share of factor i in total payments to variable factors. The first equality in (2) comes from the assumption of cost minimization while the second equality comes from taking derivatives of equation (1).

We need to assume $\mathbf{g}_{ij} = \mathbf{g}_{ji}$. We also need $\sum_j \mathbf{g}_{ij} = 0$ for the cost function to be homogeneous of degree one in input prices. If we impose constant returns to scale then we will have $\mathbf{r}_{Yi} + \sum_j \mathbf{r}_{ij} = 0$

We will assume that $\ln A$ takes the following form

$$\ln A = \mathbf{b}_k + \mathbf{b}_t t + \mathbf{e}_{kt} \quad (3)$$

where, k denotes industry and t denotes time and \mathbf{e}_{kt} is a random error term..

The technology term has industry, time and random components. We will assume that \mathbf{b}_t is positive, i.e., technology improves over time Equation (2) can then be rewritten as

$$S_i = \mathbf{a}_i + \mathbf{r}_{Yi} \ln Y + \sum_j \mathbf{g}_{ij} \ln P_j + \sum_j \mathbf{r}_{ij} \ln Z_j + (\mathbf{a}_{AP_i} \mathbf{b}_k + \mathbf{a}_{AP_i} \mathbf{b}_t t + \mathbf{a}_{AP_i} \mathbf{e}_{kt}) \quad (2')$$

Let us look at the expression for the error term (within parentheses) in equation (2') above (the industry and the time subscripts have been omitted from the other variables for the sake of clarity). The first term is an industry specific term. The second term is a function of time and will be negatively related to time variable if $\mathbf{a}_{AP_i} < 0$. A negative \mathbf{a}_{AP_i} will imply that technological change is biased against factor i . The last term within parentheses is a random term.

Equation (2') can therefore be estimated using an industry fixed effect, a time trend, log of price indices of the variable inputs and the log of capital and gross output. The actual equation to be estimated (after imposing all necessary constraints) takes the following form

$$S_i = \mathbf{a}_i + \mathbf{g}_{iS} \ln \left(\frac{w_S}{p_D} \right) + \mathbf{g}_{iU} \ln \left(\frac{w_U}{p_D} \right) + \mathbf{g}_{iM} \ln \left(\frac{p_M}{p_D} \right) + \mathbf{r}_{iK} \ln \left(\frac{K}{Y} \right) \quad (2'')$$

+ industrydummy + timetrend + error

where w denotes wage and the subscripts S and U denote skilled and unskilled labor, respectively; p denotes price of materials and the subscripts D and M denote domestic and imported, respectively; K denotes capital.

We have an equation for each of the four variable factors – skilled labor, unskilled labor, imported materials and domestic materials. These equations will be estimated as a system. Only three of these equations will be linearly independent. We will drop the share equation involving domestic materials and estimate the remaining three using iterative SURE. Since the iterative procedure is used, the estimates will not be sensitive to the equation being dropped. One point to note is that we assume that there is no correlation between capital and shocks affecting factor shares. This is reasonable since the capital stock for year T does not include investment in year T. While the latter could be correlated with year T shocks, the capital stock should not be. Also, investment may not respond year-to-year shocks since the planning horizon for new investment is likely to be longer than a year.

IV. Data and Results

Data

Our data comes from the Annual Survey of Manufactures for Peru collected by *Ministerio de Industria, Turismo, Integración y Negociaciones Comerciales Internacionales* (MITINCI). The data is available at the 4-digit ISIC (Rev 3) level and includes information on employment, wages, value added, materials, investment and capital stock for firms with 5 or more workers. The data is available from 1994 to 2000⁶. The survey covers 72 of 125 industrial sectors, representing 90 percent of the gross value of production of the base year, 1994.

⁶ Previous surveys cover the period from 1988 to 1992. However the data from these years is not easily comparable to that of the latter period because of changes in industry classification.

The survey has information on white-collar and blue-collar workers and, as mentioned before, we interpret these as skilled and unskilled labor, respectively. In order to compute payments to these two types of workers we take into account both wage and non-wage payments. The wage payments are available for each type of worker. The non-wage payments are not available separately for the two types of workers and so are allocated to each type according to their share in the wage bill. Non-wage payments include health plan payments, accident insurance, manufacturing training fund (SENATI), contributions to national housing fund (FONAVI), tenure bonus and Christmas and National Holiday bonuses.

We constructed price indices for materials in order to get estimates of the quantities of materials, both domestic and imported. We were able to obtain these indices only at the level of input-output (IO) industries for Peru. Both domestic and import price indices (base year 1994) were available at the IO level from the *Compendio Estadístico* published by the National Institute of Statistics and Information (INEI). The 1994 IO table for Peru gives the flows of both domestically produced commodities as well as imports into each industry. A price index for materials was constructed by taking the weighted average of the price indices of commodities with the 1994 shares of each commodity in total intermediate use as weights⁷. Separate price indices were computed for domestic and imported materials to deflate these two variables. The payments to these factors were the nominal values of these variables⁸.

We employed a perpetual inventory method to obtain estimates of the capital stock. That is, the beginning of period capital stock in period t , K_t , is given by

$$K_t = (1 - d)K_{t-1} + I_{t-1}$$

⁷ Note that this is the same as a Tornqvist chain price index assuming the shares of each commodity in total intermediate use stays the same over time. The Tornqvist chain price index is computed as follows:

$$\ln\left(\frac{p_T}{p_0}\right) = \sum_t \sum_i 0.5(s_{it} + s_{it-1}) \ln(p_{it} / p_{it-1})$$

where $t=1$ to T , s is the value share of commodity i (see Kohli, ch. 8).

⁸ These also include taxes on fuels. Taxes on fuels were allocated to domestic and imported materials according to their shares in total material use.

where δ is the depreciation rate and I is investment (at base year prices). The depreciation rate used for equipment was 12.25% and that for structures was 3.6% (based on US data from Jorgenson, Gollop and Fraumeni (1999), ch. 4). The initial capital stock used was the one available for 1994 from the survey⁹.

The wages of both types of labor were calculated at the level of manufacturing sector as whole for each year (obtained as total wage payments divided by total employment). The assumption here is that wages are the same across industries due to mobility of both types of labor, which has been the standard practice in the literature¹⁰. Wages, therefore, vary only across time. The wage variables used in the regression are indices with 1994 as base.

Estimation

The sample period for all regressions is 1995-2000¹¹. Before we estimate equation (2'') we run a regression involving the share of skilled workers in the total wage bill as the dependent variable. This has been the standard way to analyze the determinants of the changing share of skilled workers (see, for example, Berman Bound and Griliches (1994) and Pavcnik (2003)). The equation takes the following form.

⁹ The survey reports the end of the year capital stock and investment during that year. The beginning of the year capital stock for 1994 was estimated using the investment data for 1994 and the depreciation rates used. The capital stock for subsequent years was estimated using the perpetual inventory method mentioned before. One problem with the capital data for 1994 is that the survey reports the capital stock data at book value. This can introduce both upward and downward biases in the capital stock measure. The capital stock may be overstated since depreciation is not taken into account. The stock may be understated since investment acquired in years prior to 1994 will be valued at the prices of the years they were acquired instead of 1994 prices and prices tend to increase over time (see Roberts (1996)). The problem may be alleviated somewhat by the fixed effects.

¹⁰ Since observed wages do differ across industries, the implicit assumption here is that such variations arise from differences in quality and that the *quality adjusted* wage is the same across industries. Actual industry wages cannot be used in the regression since they are endogenous.

¹¹ We do not include 1994 in our sample since the mismeasurement problem is likely to be more severe with the capital stock data for 1994.

$$S' = a + b_1 \ln\left(\frac{w_S}{w_U}\right) + b_2 \ln\left(\frac{K}{V}\right)$$

where S' is the share of skilled workers in total wage bill, w_S and w_U are wages of skilled and unskilled labor, respectively, K is capital and V is value added.

The theoretical basis of the equation is a quasi-fixed translog function for value added with the usual homogeneity restrictions and constant returns to scale assumption imposed. Capital is taken to be the fixed input while the two types of labor are variable. The results of this estimation, with and without a time trend, are reported in table 3b. The relative wage is assumed to be the same across industries in a given year. The capital to value added ratio is significant at the 10% level. The time variable is positively related to the skilled share but is not significant.

One problem with this specification could be that the production function is not separable between labor and capital variables on one hand and materials on the other. The equation could, therefore, be misspecified. We will show later that the null hypothesis of separability is rejected by the data.

We now go back to the share equations based on our frame work involving a gross output cost function. Equation (2'') gives us a system of equations, one for each variable factor of production. Before we estimate the entire system of equations we estimate an equation involving the difference in the share of skilled workers and unskilled workers using equation (2''). That is, we estimate an equation of the following form

$$\begin{aligned} S_S - S_U = & (\mathbf{a}_S - \mathbf{a}_U) + (\mathbf{g}_{SS} - \mathbf{g}_{US}) \ln\left(\frac{w_S}{p_D}\right) + (\mathbf{g}_{SU} - \mathbf{g}_{UU}) \ln\left(\frac{w_U}{p_D}\right) \\ & + (\mathbf{g}_{SM} - \mathbf{g}_{UM}) \ln\left(\frac{p_M}{p_D}\right) + (\mathbf{r}_{SK} - \mathbf{r}_{UK}) \ln\left(\frac{K}{Y}\right) \\ & + \text{industrydummy} + \text{timetrend} + \text{error} \end{aligned} \quad (4)$$

The results are reported in the first column of table 4b. The capital-output ratio is highly correlated with the difference between skilled and unskilled wage share. An increase in the capital to output ratio of 10% will increase the difference in the share by 0.1 percentage points, which is about 4% of the mean share difference.

Figure 2 plots the change in the difference between skilled and unskilled wage against change in the log of capital stock over the period 1995-2000. There is a very clear positive relationship between the two variables.

We next run the system of equations described by (2'') using iterative SURE. The results for the skilled and unskilled wage share equations are reported in the last two columns of table 4b. Both skilled and unskilled wage shares are positively related to the capital to output ratio. However, the point estimate is higher in the skilled wage share regression. The difference in the estimates between the skilled and unskilled wage share is 0.011, which is consistent with the results reported in the first column of the table. It is interesting to note that technological change, as measured by the time variable, has been biased against both skilled and unskilled workers. The negative bias is stronger for unskilled workers. However, the relationship with the shares is weaker compared to capital. It is also interesting to note that the relative price of imported materials is actually positively related to the skilled wage share indicating these two factors may be substitutes. Unskilled wage shares appear to increase with a decrease in price of imported materials. All this is consistent with the hypothesis that imported materials may embody skilled labor for developing countries. The coefficients for price of imported materials are however not significant.

How much can capital accumulation explain?

We want to estimate how much of the increase in share of skilled workers and their relative wages over the 1995-2000 period can be explained by accumulation of

capital. The share of skilled workers in the *wage bill* is equal to $S_S/(S_S+S_U)$, where S_S and S_U are the shares of skilled and unskilled workers in the payments to all variable factors. We estimate the changes in the skilled and unskilled shares in total factor payments between 1995-2000 predicted by the increase in the capital stock for each industry using the results of the SURE regression reported in table 4b. These estimates are then used to obtain the corresponding changes in skilled share in the wage bill. The actual and estimated mean changes (across industries) of the skilled share in the wage bill are reported in the first panel of table 5. As can be seen, capital accumulation explains the entire increase in the mean wage bill share of skilled workers.

We also want to estimate how much of the increase in the share of skilled workers in the manufacturing sector as a whole can be explained by capital accumulation. Increases in the capital stock have increased the within industry wage shares of skilled labor. As was shown in section II, the change in the overall share of skilled workers in the wage bill of the manufacturing sector can be decomposed into a within industry component and a between industry component. We want to see how much capital accumulation has contributed to the within industry component. This contribution is equal to $\sum \bar{P}_i \Delta \hat{S}'_i$ where \bar{P}_i is the mean (over the time period) share of industry i in total wages and \hat{S}'_i is the predicted share of skilled labor in the wage bill for industry i , obtained using the coefficients of the SURE regression and changes in the capital stock. That is, we calculate weighted sum of the changes in the skilled wage share predicted by capital accumulation. This contribution and the actual change in the skilled wage share in the manufacturing sector are reported in the second panel of table 5. Capital accumulation explains close to 60% of the increase in the skilled wage share in the manufacturing sector as a whole.

We also want to see how much of the increase in relative wages in the manufacturing sector as a whole can be explained by increases in capital. This is done by using the fact that $\Delta \log(w_S/w_U) = \Delta \log(S'_S/S'_U) - \Delta \log(n_S/n_U)$, where w denotes wage, S' denotes share in wage bill and n denotes employment. We can estimate how much the

relative wages would have to change given the changes in the shares of skilled and unskilled workers predicted by capital accumulation. We take the change in the (log) employment ratio as given and equal to the actual change. The predicted and actual changes in (log) relative wages are reported in the last panel of table 5. Capital stock increases explain about 65% of the actual change in relative wages in the manufacturing sector.

Separability

As mentioned before, share equations based on value added function could be misspecified since the assumption of separability may not be valid. This could be one reason why we see a weaker relationship between capital intensity and skilled labor demand in the share equation involving value added.

We can have a value added function that depends only on capital and labor only if the gross output function is of the following form

$$Y(S, U, K, M) = Y(V(S, U, K), M)$$

where Y is gross output, V is real value added. S, U and K are skilled labor, unskilled labor and capital, respectively and M is a vector of materials (domestic and imported).

The cost function will be separable between the prices of labor and capital inputs on one hand and material inputs prices on the other if the production function is separable with respect to these two sets of inputs (as shown above). A cost function, c, is said to be separable with respect to a partition of inputs if the following holds

$$\frac{\partial(c_j / c_k)}{\partial p_M} = 0$$

where the subscripts for the cost function denote partial derivatives, j and k denote inputs belonging to one subset resulting from the partition and p_M is the price of input m belonging to the other subset (see Kohli (1991), ch. 4). That is, the ratio of quantities of inputs belonging to one subset of the partition should be independent of the prices of inputs of the other subset. This would require, e.g., in the case where capital (K) and labor (L) are separable from materials (M), the following

$$s_{KM} = s_{LM}$$

where s denotes the Allen-Uzawa elasticity of substitution.

The condition stated above refers to the total cost function where all inputs are variable. Since we estimate a quasi-fixed cost function, we need to relate our estimates to the parameters of the total cost function. Brown and Christensen (1981) show how this can be done. It can be shown that a sufficient condition for separability to hold is the following for the system of equations described by (2'')

$$g_{SM} = g_{UM} = g_{SD} = g_{UD} = r_{KM} = 0$$

We test this restriction using the likelihood ratio test. The results are reported in table 6. The likelihood ratio statistic is 18.3, which is greater than the critical value of the χ^2 distribution at the 1% level. The null hypothesis that the separability restrictions hold is therefore rejected.

V. Conclusion

We show in this paper that there has been a substantial shift in demand in favor of skilled workers in Peru during the latter half the 1990s. This increase in demand has been observed in other developing countries as well in recent years. There is a widely held view that unobserved skilled biased technological change is behind this development. We show in this paper that capital accumulation, and not unobserved technology, can explain

most of this shift towards skilled labor in Peru, after taking into account the effect of other factors including materials.

The shift in demand towards skilled labor has been observed in both developing and developed countries. While there are similarities associated with this phenomenon between these two sets of countries, there could be important differences. We observe, for example, that the employment ratio has not changed much in Peru while that is not the case in the US. Also, there is a sharp increase in capital intensity in Peru, which we do not observe in the US. This latter difference could explain why we see that capital accumulation can explain a large fraction of the shift in demand towards skilled labor in Peru but not in the US. One implication of our results is that if trade stimulates investment in developing countries then it could also increase the relative demand for skilled labor in the presence of strong capital-skill complementarities.
